**TRACE METALS IN CLAMS (*MACOMA BALTHICA*) AND SEDIMENTS
AT THE PALO ALTO MUDFLAT IN SOUTH SAN FRANCISCO BAY:
JUNE 1992 - MAY 1993**

By Samuel N. Luoma, Daniel J. Cain, Cynthia Brown and Michelle Hornberger

ABSTRACT

This report presents trace element concentrations analyzed on samples of sediment and clams (*Macoma balthica*) collected from a mudflat one kilometer south of the discharge of the Palo Alto sewage treatment works. Samples were collected on ten occasions between June, 1992 and May 1993, at near monthly intervals. Previous reports compared concentrations of silver and copper from this mudflat with values observed at other stations in San Francisco Bay in earlier studies. Changes in concentrations of these metals were also compared from near monthly collections between 1977 and 1992. In this report we update this data set, emphasizing the recent data, changes observed between 1986 and 1993, and trends in copper and silver concentrations in the last three years.

INTRODUCTION

Sediments and benthic organisms are commonly employed to determine spatial distributions and temporal trends of trace metal contamination in estuarine waters. Sediments bind metals strongly, removing them from solution. The result is that sediments may retain the metals released to an environment. Thus concentrations of metals in sediments may be indicative of anthropogenic releases, with at least some integration over time.

Metals in sediments are also indicative of the exposure of animals in contact with benthic and suspended particulate materials. However, it is not well known what proportion of sediment-bound metal is passed on to living organisms. In order to better estimate bioavailable metal exposures, the tissues of the organisms themselves may be analyzed for trace metals. Biological species concentrate most metals to levels higher than occur in solution, and may even be more sensitive indicators of anthropogenic metal inputs than are sediments. Different species concentrate metals to different degrees. If one species is analyzed consistently the results can be successfully employed to indicate trace element exposures to the food web of the organism. For example, Ag, Cu and Se contamination originally observed in clams (*Macoma balthica*) at a Palo Alto mudflat was later also found in diving ducks, snails, and mussels from that area.

Purpose

The purpose of this study is to present trace metal concentrations observed in sediments and clams at a mudflat in south San Francisco Bay. The station, termed here the Palo Alto mudflat, is located one kilometer south of the intertidal discharge point of the Palo Alto publicly-owned treatment works (POTW). The data reported here are from samples collected on eleven dates between June 1992 and May

1993. These data and data collected from earlier studies will be used to approach three questions:

1. What are concentrations of Ag, Cd, Cr, Cu, Ni, Pb, V and Zn in clams that reside in sediments at the Palo Alto mudflat and in sediments from that site?
2. How do concentrations and seasonal trends of metals in clams and sediments at Palo Alto in 1992-93 compare with concentrations observed in 1990-91 and 1991-92?
3. What are the trends in copper and silver concentrations at the Palo Alto mudflat between 1986 and 1993? Specifically, are concentrations of these elements in 1992-93 changing compared to concentrations observed at this locality in recent years?

Study Site

The data from this study were collected from site 3 of the transect conducted by Thomson and others (1984) along the Palo Alto shoreline, as reported by Luoma and others (1991; 1992). The highest concentrations of copper and silver were observed in clams and sediments adjacent to the Palo Alto POTW discharge by Thomson and others (1984). Contamination also was observed at the site that is being monitored by Luoma and others (1991; 1992). The influence of the POTW on metal concentrations at site 3 also was demonstrated by Cain and Luoma (1990), who showed a similarity in temporal trends at site 3 between metal discharge from the POTW and concentrations in clam tissues. Results from both studies thus indicated that environmental metal concentrations at site 3 were indicative of POTW metal discharges.

Another important conclusion from Cain and Luoma (1990) and Luoma and others (1985) was that concentrations of metals fluctuated on nearly monthly time scales in the Palo Alto mudflat environment. Thus frequent sampling within a year was necessary to characterize contamination for that year. The data presented in this report follow those procedures.

SAMPLING PROCEDURES

All samples were collected from the exposed mudflat at low tide. Sediment samples were scraped from the surface oxidized layers (1 -2 cm) of mudflat. Thus, these samples represent recently deposited sediments, or sediments affected by recent chemical reactions. Sediments were immediately returned to the laboratory in Menlo Park after collection. There they were sieved through 100 micrometer polyethylene mesh to remove large grains that might bias interpretation of concentrations. In previous years sieving was done with ocean water diluted to ambient salinities. In December 1992 we began sieving with distilled water after rigorous preliminary studies showed no difference between the two approaches. The mesh size was chosen by the largest grains typically found in the digestive tract of the indicator organism *Macoma balthica*. Previous studies have shown little difference between sieved and unsieved sediments in the silt-clay type sediment that predominates at this station, but sieving reduces the likelihood that changes are the result of sampling sediments of different character.

Before December 1992 the sieved slurry was subsampled using procedures reported by Luoma and others (1991; 1992). Beginning in December 1992, the mass of sediments that did not pass the sieve was weighed. Those that passed through the sieve were dried at room temperature, then 0.250 to 0.500 gram aliquots were collected in replicate for analysis. The greater weight enhanced detection limits for elements that occur in low concentrations. The subsamples were dried at 60° celsius before weighing and

extraction. The replicate subsamples were digested for "total" metal analysis by refluxing in 10 milliliters of concentrated nitric acid until the digest was clear. Samples were then evaporated to dryness and reconstituted in dilute (5 percent) hydrochloric acid for analysis. The hydrochloric acid matrix was specifically chosen because it mobilizes Ag into solution through creation of Ag-chloro complexes. Another set of replicate samples was subjected to a partial weak acid extraction, as a crude chemical estimate of bioavailable metal. These subsamples were extracted for 2 hours with 10 mL of five percent hydrochloric acid at room temperature. The extract was then pressure filtered through a 0.45 micrometer membrane filter.

The deposit feeding clam *Macoma balthica* was collected simultaneously with the sediment samples. More than 40 individuals were collected at each sampling, and the range of sizes (shell length) was maximized by intensive field sampling. Animals were returned to the laboratory and held for 48 hours in ocean water diluted to the ambient salinity at the time of sampling. This was done to depurate undigested material from their digestive tracts. After depuration the individual clams were separated into size classes (determined by differences of one millimeter shell length). Each size class was composited for a single sample, and soft tissues were removed for analysis. Samples for each date thus were composed of eight to twelve replicate composites, with each composite consisting of animals of a similar shell length. Animal samples were dried, weighed and refluxed in concentrated nitric acid until the digest was clear. Digests were then dried and reconstituted in dilute (5 percent) hydrochloric acid for analysis.

All metal analyses were conducted by Inductively Coupled Argon Plasma Emission Spectroscopy (ICAPES). Selected tissue samples were also analyzed by Atomic Absorption Spectroscopy to compare with the results of ICAPES analysis. Data from the two types of analyses were not significantly different ($p>0.10$). Analyses of National Institute of Technical Standards (NITS) reference materials (bovine liver, oyster tissue) were also routinely conducted to assure adequate recovery and accurate analyses. Values were within the acceptable range reported by NITS. Peaks were censored from the data if they did not exceed 10 times the standard deviation of the background (this is termed the limit of quantification), with the exception of silver in sediments. Silver peaks were censored if they did not exceed 3 standard deviations (limit of detection). Most detectable silver concentrations from sediments fell between the limit of detection and limit of quantification.

RESULTS OF ANALYSES

Appendix 1 lists all sediment analyses, and Appendix 2 lists all metal analyses of clam tissues conducted from the June 1992 to May 1993 samples. Analytical data and detection limits also are given for each sample to aid in verification of peaks. Statistical data indicates size influences on tissue concentrations, and content calculations are reported with summary statistics in Appendix 2.

Table 1 lists monthly variability in mean silver and copper concentrations observed in clams and sediments from the study site between June 1992 and May 1993. Tables 2 and 3 compare the 1992 - 93 data to long-term temporal trends observed in the copper and silver concentrations of clams since 1977. These data are annual mean concentrations calculated from the 7 to 11 samples collected between May of one year and May of the next (for example the "1993" data represent collections from May 1992 through May 1993). Figures 1, 2 and 3 illustrate the trends in these data among recent years, so as to better put perspective on changes in 1993. From these figures and tables the data collected in 1993 can be compared with earlier levels of contamination at this station.

Seasonal trends in silver concentrations are compared between 1991, 1992 and 1993 data sets (figure 4). Figure 5 shows silver content in clams during the three years, a data manipulation that allows eliminating the effects of growth. This approach allows demonstration that the differences between the years were not the result of different biological processes.

Metal concentrations in sediments over the period May 1990 through May 1993 were compared with those in clams. The seasonal record allows detection of anomalous metal inputs to the sediments as observed in March 1992 (fig. 6; full data set reported in Luoma and others, 1992). Figure 7 shows the same data for additional metals such as chromium and vanadium, which were not heretofore contamination problems at the Palo Alto site. Silver concentrations in sediments are shown in figure 8. A number of values are missing from the figure for 1991, because concentrations during most of that year were below detection limits. After the March 1992 pulse of metal input, slightly higher silver concentrations were retained, thus making them detectable. The rapid decline in silver concentrations in February, March and May of 1993 was detectable because of the new approach of analyzing a larger mass of sediment. Copper and silver concentrations in clams are compared with concentrations in sediments in figures 6 and 8. The higher values in clams occur following the pulse of metal input and are retained until Spring 1993. Figure 9 compares total copper with hydrochloric acid-extractable, bioavailable copper, in order to further elucidate the nature of pulse metal input to the sediments.

Figure 10 shows the condition index for clams during the 1990 through 1993 period. Condition index is the tissue weight of a clam of a given length (the "fatness" index), and is an index of the clams well-being. *Macoma balthica* from San Francisco Bay typically show dual periods of growth in spring and fall, as observed in calendar year 1991 in figure 10. After the pulse of metal input to sediments, and during the 1992 and 1993 period of elevated tissue concentrations, those growth peaks were absent. Growth returned when tissue metal concentrations declined rapidly in March and May, 1993.

LIST OF FIGURES

- Figure 1. Annual mean concentrations of silver in clams (in micrograms per gram dry weight soft tissue) from May to May of each year from 1985-86 to 1992-93. Each annual mean is derived from seven to eleven collections at near-monthly intervals in each year. Vertical bars represent \pm one standard deviation from replicate composite samples.
- Figure 2. Annual mean concentrations of silver in clams (in micrograms per gram dry weight soft tissue) from May to May of each year from 1988-89 to 1992-93. Each annual mean is derived from seven to eleven collections at near-monthly intervals in each year. Vertical bars represent \pm one standard deviation from replicate composite samples.
- Figure 3. Annual mean concentrations of copper in clams (in micrograms per gram dry weight soft tissue) from May to May of each year from 1985-86 to 1992-93. Each annual mean is derived from seven to eleven collections at near-monthly intervals in each year. Vertical bars represent \pm one standard deviation from replicate composite samples.
- Figure 4. Silver concentrations in *Macoma balthica* clams (in micrograms per gram dry weight of soft tissues) as observed at near-monthly intervals between May and May in 1990 through 1993. Vertical bars represent \pm one standard deviation from replicate composite samples. Some vertical bars are smaller than the symbol.
- Figure 5. Silver content (in micrograms) of a *Macoma balthica* clam of 25 millimeter shell length as observed at near-monthly intervals between May and May in 1990 through 1993. This data is calculated from Figure 4 and the relationship in each collection between tissue weight and shell length for individual samples.
- Figure 6. Copper concentrations in *Macoma balthica* clams (in micrograms per gram dry weight of soft tissues) as observed at near-monthly intervals between May 1990 and May 1993. The right Y axis show copper concentrations in sediments through the same time period. Vertical bars represent \pm one standard deviation from replicate composite clam samples. Values for replicate analysis of copper samples are shown in Appendix 1.
- Figure 7. Concentrations of chromium, iron and vanadium in sediments (in micrograms per gram dry weight) as observed at near-monthly intervals between May 1990 and May 1993. Iron and chromium are hydrochloric acid extractable. Values for replicate analysis of samples are shown in Appendix 1.
- Figure 8. Silver concentrations in *Macoma balthica* clams (in micrograms per gram dry weight of soft tissues) as observed at near-monthly intervals between May 1990 and May 1993. The right Y axis show silver concentrations in sediments through the same time period. Vertical bars represent \pm one standard deviation from replicate composite clam samples. Values for replicate analysis of copper samples are shown in Appendix 1.
- Figure 9. Hydrochloric acid extractable and total copper concentrations in sediments (in micrograms per gram dry weight) as observed between May 1990 and May 1993 at Palo Alto. Values for replicate analysis of copper samples are shown in Appendix 1.

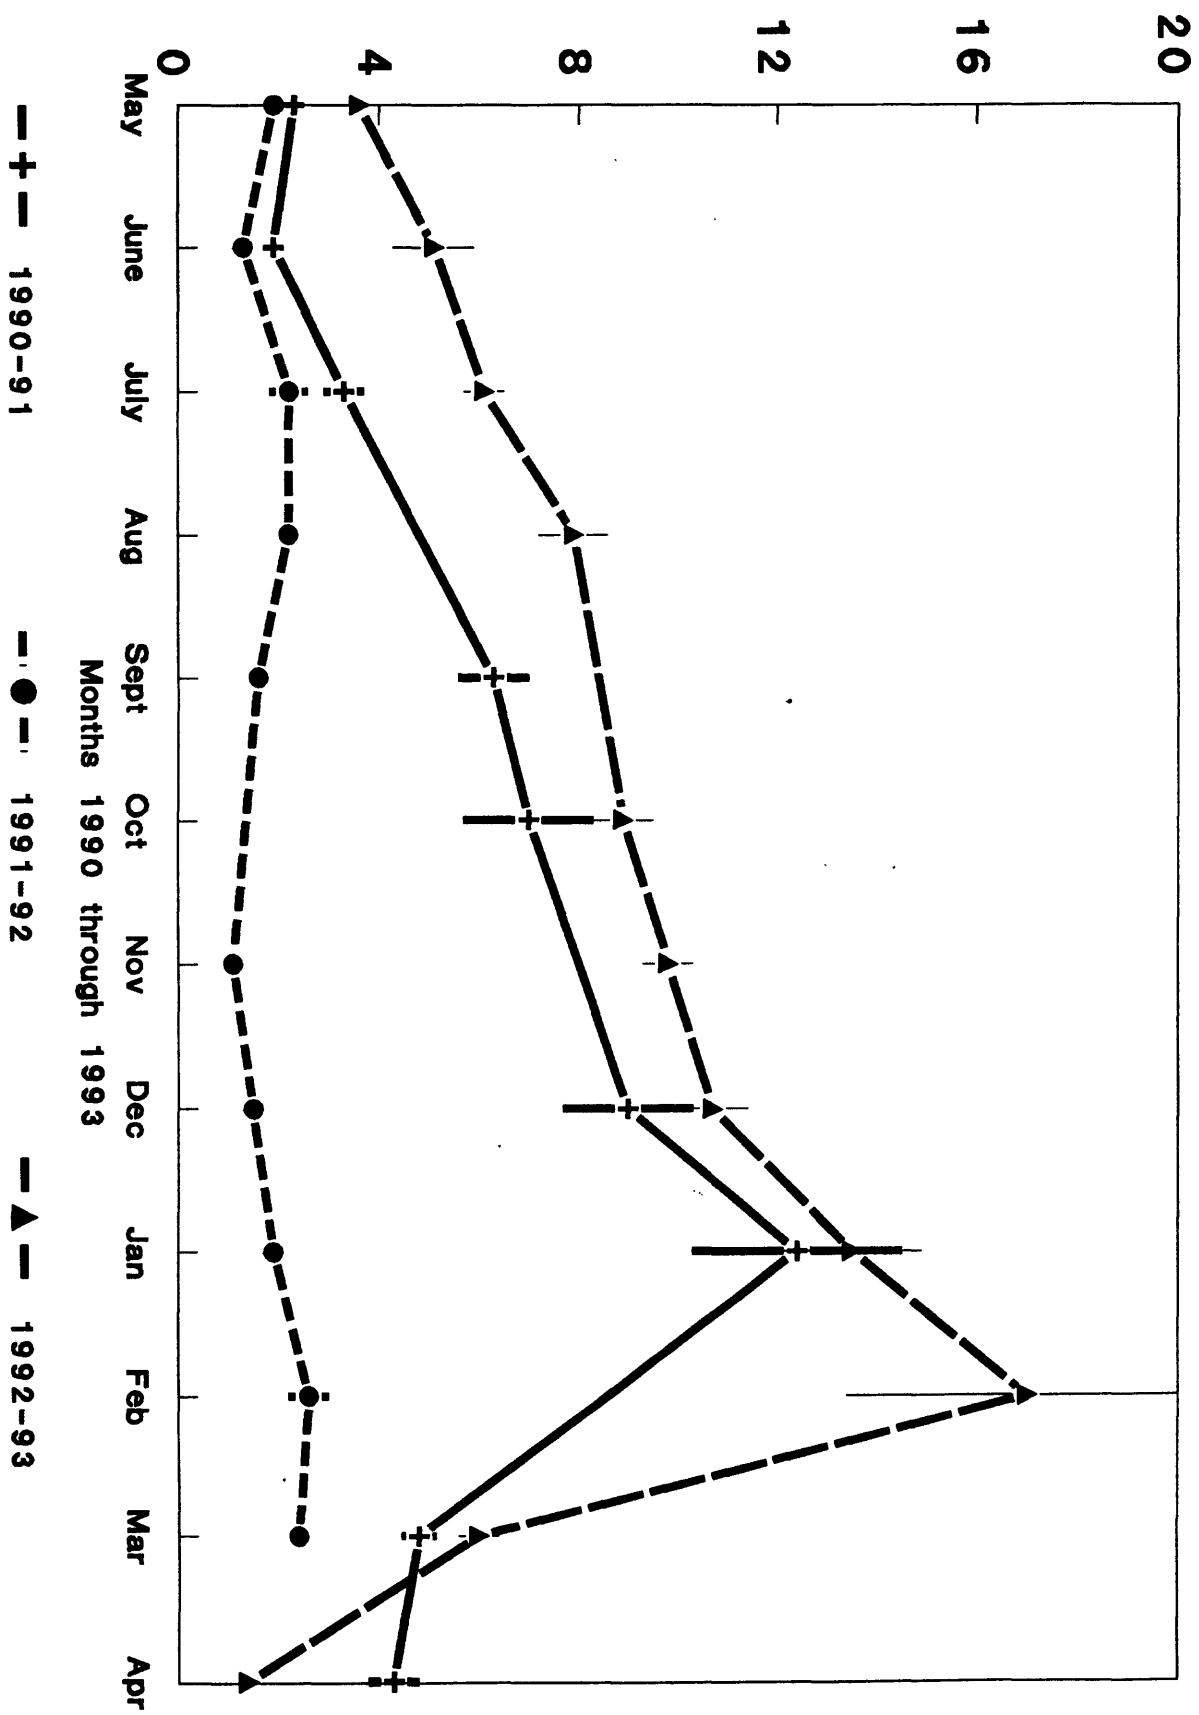

Figure 10. Weight of a *Macoma balthica* clam of 20 millimeter shell length between May 1990 and May 1993 at Palo Alto. Weights interpolated from regression of dry tissue weight against shell length for individual samples from each sample collection.

APPENDIX 1. Metal concentrations in sediments collected at the Palo Alto mudflat. Each monthly collection is reported on a separate page. Concentrations observed in the reconstituted samples or extracts (in micrograms per milliliter or ug/ml) are reported at the top of each page, along with the sediment weight and dilution factor. The latter are employed to determine concentrations in sediments (reported as microgram per gram dry sediment or $\mu\text{g/g}$). Replicate subsamples were analyzed from each collection. Mean and standard deviation for the replicate samples are reported for the total and hydrochloric acid extracts.

APPENDIX 2. Metal concentrations in the clam *Macoma balthica* collected at the Palo Alto Mudflat. Each monthly collection is reported on two pages. The first page contains summary statistics:

Mean concentrations in microgram per gram dry tissue weight (ug/g).

STD is the standard deviation of the mean.

SEM is the standard error of the mean.

CV percent is the coefficient of variation.

r wt x [] is the correlation coefficient for the concentration versus weight correlation for each element.

X 100mg is the concentration interpolated from the above regression for a 100 mg animal.

r 1 x [] is the correlation coefficient for the concentration versus shell length regression.

X 20 mm and X 25 mm are concentrations interpolated from the regression for 20mm and 25 mm animals.

Content (a measure of metal bioaccumulation that is independent of mass) is also shown for 20 and 25 mm animals, as is the weight determined for animals of 15 mm and 20 mm shell length.

The second page for each month shows each analysis of each composite sample, the number of animals composited in each, concentration as calculated from sample dry weight and the dilution factor and the metal content for each sample.
